3

Abstract

The influence of electronic screens on children and adolescents' health and education is not

well understood. In this review, we harmonised 255 effects representing unique combinations

of exposures and outcomes from 103 meta-analyses (2,496 primary studies; 2,026,054 31

participants). Some types of screen use, such as social media, were consistently correlated 32

with risks to health. However, other forms of screen use showed associations with benefits. 33

For example, experimental evidence showed that video games improve aspects of cognitive

function. Some types of screen use have complex associations with outcomes. For example,

general screen use (i.e., content not indicated) showed correlations with harm for body

composition, depression, and learning. However, when parents watched with their children or

the content was educational, general screen use was associated with greater learning. More

nuanced guidelines are needed to help parents, teachers, and practitioners ensure that youth

benefit from their interactions with screens.

An umbrella review of the benefits and risks associated with youths' interactions with electronic screens

#### Introduction

45

In the 16th century, hysteria reigned around a new technology that threatened to be

"confusing and harmful" to the mind. The cause of such concern? The widespread

availability of books brought about by the invention of the printing press. In the early 19th

century, concerns about schooling "exhausting the children's brains" followed, with the

medical community accepting that excessive study could be a cause of madness. By the

20th century, the invention of the radio was accompanied by assertions that it would distract

children from their reading (which by this point was no longer considered confusing and

harmful) leading to impaired learning.

Today, the same arguments that were once levelled against reading, schooling, and radio are being made about screen use (e.g., television, mobile phones, and computers).<sup>4</sup>
Excessive screen use is the number one concern parents in Western countries have about their children's health and behaviour, ahead of nutrition, bullying, and physical inactivity.<sup>5</sup>
Yet, the evidence to support parents' concerns is inadequate. A Lancet editorial<sup>6</sup> suggested that, "Our understanding of the benefits, harms, and risks of our rapidly changing digital landscape is sorely lacking."

While some forms of screen use (e.g., television viewing) may be detrimental to health and wellbeing, <sup>7,8</sup> evidence for other forms of screen exposure (e.g., video games or online communication, such as Zoom<sup>TM</sup>) remains less certain and, in some cases, may even be beneficial. <sup>9,10</sup> Thus, according to a Nature Human Behaviour editorial, research to determine the effect of screen exposure on youth is "a defining question of our age". <sup>11</sup> With concerns over the impact of screen use including education, health, social development, and psychological well-being, an overview that identifies potential benefits and risks is needed.

Citing the negative effects of screens on health (e.g., increased risk of obesity) and 68 health-related behaviours (e.g., sleep), guidelines from the World Health Organisation<sup>12</sup> and 69 numerous government agencies<sup>13,14</sup> and statements by expert groups<sup>15</sup> have recommended that young people's time spent using electronic media devices for entertainment purposes 71 should be limited. For example, the Australian Government guidelines regarding sedentary behaviour recommend that young children (under the age of two) should not spend any time watching screens. They also recommend that children aged 2-5 years should spend no more than one hour engaged in recreational sedentary screen use per day, while children aged 5-12 and adolescents should spend no more than two hours. However, recent evidence suggests that longer exposures may not have adverse effects on children's behaviour or mental health—and might, in fact, benefit their well-being—as long as exposure does not reach extreme levels (e.g., 7 hours per day)<sup>16</sup>. Some research also indicates that content (e.g., video games vs television programs) plays an important role in determining the potential benefit or harm of youths' exposure to screen-based media. <sup>17</sup> Indeed, educational screen use is positively related to educational outcomes. 18 This evidence has led some researchers to argue that a more nuanced approach to screen use guidelines is required. 19

In 2016, the American Academy of Pediatrics used a narrative review to examine the
benefits and risks of children and adolescents' electronic media<sup>20</sup> as a basis for updating their
guidelines about screen use.<sup>15</sup> Since then, a large number of systematic reviews and
meta-analyses have provided evidence about the potential benefits and risks of screen use.
While there have been other overviews of reviews on screen use, these have tended to focus
on a single domain (e.g., health<sup>21</sup>), focus on a particular exposure (e.g., social media<sup>22,23</sup>) or
provide only a narrative summary of the literature.<sup>24</sup> Focusing on a single domain or
exposure makes it difficult to understand what trade-offs are involved in any guidelines
around screen use. For example, prohibiting screen use might reduce exposure to advertising
but may also thwart learning opportunities from interactive educational tools. Reviews on
either of these exposures or outcomes would likely miss being able to quantify these

trade-offs. Overviews are one method of evidence synthesis that helps address these trade-offs, by providing 'user-friendly' summaries of a field of research.<sup>25</sup> These overviews provide a reference point for the field and allow for easier comparison of risks and benefits for the same behaviour. By analogy, reading is a sedentary behaviour, and only by comparing the health risks against the educational benefits can researchers and policymakers make clear recommendations about what young people should do.

In order to synthesise the evidence and support further evidence-based guideline 101 development and refinement, we reviewed published meta-analyses examining the effects of 102 screen use on children and youth. This review synthesises evidence on any outcome of 103 electronic media exposure. We deliberately did not pre-specify outcomes, in order to get a 104 comprehensive list of areas where there is meta-analytical evidence. Adopting this broad 105 approach allowed us to provide a holistic perspective on the influence of screens on children's 106 lives. By synthesising across life domains (e.g., school and home), this review provides 107 evidence to inform guidelines and advice for parents, teachers, pediatricians and other 108 professionals in order to maximise human functioning. 109

110 Results

The searches yielded 50,649 results, of which 28,675 were duplicates. After screening titles and abstracts, we assessed 2,557 full-texts for inclusion. Of those, 218 met the inclusion criteria and we extracted the data from all of these meta-analyses. Figure 1 presents the full results of the selection process.

The most frequently reported exposures were physically active video games (n = 31), 115 general screen use (n = 27), general TV programs and movies (n = 20), and screen-based 116 interventions to promote health (n = 14). Supplementary File 5 provides a list of all 117 exposures identified. The most frequently reported outcomes were body composition (n =118 30), general learning (n=25), depression (n=13), and general literacy (n=12). Of the 119 274 unique exposure/outcome combinations, 242 occurred in only one review, with 23 appearing twice, and 9 appearing three or more times. Full characteristics of the included studies are provided in Table 1. After removing reviews with duplicate exposure/outcome 122 combinations, our process yielded 255 unique effect/outcome combinations (retaining 123 multiple effects for different age groups or study designs) contributed from 103 reviews. 124 These effects represent the findings of 2,496 primary studies, involving 2,026,054 participants. 125 The characteristics of the included effects are available in Supplementary File 9. 126

#### TABLE 1

127

The quality of the included meta-analyses was mixed (see Table 1). Most assessed 128 heterogeneity (n low risk = 94/103, 91% of meta-analyses), reported the characteristics of 129 the included studies (n low risk = 87/103, 84%), and used a comprehensive and systematic 130 search strategy (n low risk = 72/103, 70%). Most reviews did not clearly report if their 131 eligibility criteria were predefined (n unclear = 72/103, 70%). Many papers also did not 132 complete dual independent screening of abstracts and full text (n high risk = 20/103, 19%) 133 or did not clearly report the method of screening (n unclear = 38/103, 37%). A similar trend 134 was observed for dual independent quality assessment (n high risk = 53/103, 51%; n high risk 135

 $_{136} = 19/103, 18\%$ ). Overall, only 7 meta-analyses were graded as low risk of bias on all criteria.

There were 89 unique effects associated with education outcomes, including general 137 learning outcomes, literacy, numeracy, and science. We removed 28 effects that did not 138 provide individual study-level data, 19 effects with samples < 1,000, and 19 effects with a 139 significant Egger's test or insufficient studies to conduct the test. Effects not meeting one or 140 more of these standards are presented in Supplementary File 6. The remaining 23 effects met 141 our criteria for statistical credibility and are described in Figure 2. These 23 effects came 142 from 18 meta-analytic reviews analysing data from 338 empirical studies with 262,537 143 individual participants. 144

Among the statistically credible effects, general screen use, television viewing, and 145 video games were all negatively associated with learning. E-books that included narration, 146 as well as touch screen education interventions, and augmented reality education 147 interventions were positively associated with learning. General screen use was negatively 148 associated with literacy outcomes. However, if the screen use involved co-viewing (e.g., 149 watching with a parent), or the content of television programs was educational, the 150 association with literacy was positive and significant at the 95% confidence level (weak 151 evidence). Numeracy outcomes were positively associated with screen-based mathematics 152 interventions and video games that contained numeracy content.

As shown in Figure 2, most of the credible results (14 of 23 effects) showed statistically significant associations, with 99.9% confidence intervals not encompassing zero (strong evidence). The remaining six associations were significant at the 95% confidence level (weak evidence). All credible effects related to education outcomes were small-to-moderate.

Screen-based interventions designed to influence an outcome (e.g., a computer based program designed to enhance learning<sup>26</sup>) tended to have larger effect sizes than exposures that were not specifically intended to influence any of the measured outcomes (e.g., the association between television viewing and learning<sup>27</sup>). The largest effect size observed was

for augmented reality-based education interventions on general learning (r = 0.33, k = 15, N = 1,474). Most effects showed high levels of heterogeneity (18 of 23 with  $I^2 > 50\%$ ).

We identified 165 unique outcome-exposure combinations associated with health or 165 health-related behaviour outcomes. We removed 41 effects that did not provide individual 166 study-level data, 50 effects with samples < 1,000, and 53 effects with a significant Egger's 167 test or insufficient studies to conduct the test. No remaining studies showed evidence of 168 excessive significance. Effects not meeting one or more of these standards are presented in 169 Supplementary File 7. The remaining 21 meta-analytic associations met our criteria for 170 credible evidence and are described below (see also Figure 3). These 21 effects came from 15 171 meta-analytic reviews analysing data from 344 empirical studies with 859,562 individual 172 participants. 173

Digital advertising of unhealthy foods—both traditional advertising and video games 174 developed by a brand for promotion—were associated with higher unhealthy food intake. 175 Social media use and sexual content were positively associated with risky behaviors (e.g., 176 sexual activity, risk taking, and substance abuse). General screen use was positively 177 associated with depression, with stronger associations observed for adolescents than other 178 groups. Television viewing was negatively correlated with sleep duration, but with stronger evidence only observed for younger children. All forms of screen use (general, television, and video games) were associated with body composition (e.g., higher BMI). Screen-based 181 interventions which target health behaviours appeared mostly effective. 182

Across the health outcomes, most (14 of 21) effects were statistically significant at the 99.9% confidence interval level, with the remaining four significant at 95% confidence. However, most of the credible effects exhibited high levels of heterogeneity, with all but two having  $I^2 > 75\%$ . Additionally, most effects were small, with the association between screen use and sleep duration the largest at r = -0.37 (k = 10, N = 56, 720). Most of the effect

sizes (17/21) had an absolute value of r < 0.2.

189 Discussion

The primary goal of this review was to provide a holistic perspective on the influence of screens on children's lives across a broad range of outcomes. We found that when meta-analyses examined general screen use, and did not specify the content, context or device, there was strong evidence showing potentially harmful associations with general learning, literacy, body composition, and depression. However, when meta-analyses included a more nuanced examination of exposures, a more complex picture appeared.

As an example, consider children watching television programs—an often cited form of 196 screen use harm. We found statistically robust evidence for a small association with poorer 197 academic performance and literacy skills for general television watching<sup>27</sup>. However, we also 198 found evidence that if the content of the program was educational, or the child was watching 199 the program with a parent (i.e., co-viewing), this exposure was instead associated with 200 better literacy.<sup>28</sup> Thus, parents may play an important role in selecting content that is likely 201 to benefit their children or, perhaps, interact with their children in ways that may foster 202 literacy (e.g., asking their children questions about the program). Similar nuanced findings 203 were observed for video games. The credible evidence we identified showed that video game 204 playing was associated with poorer body composition and learning.<sup>27,29</sup> However, when the 205 video game were designed specifically to teach numeracy, playing these games showed 206 learning benefits.<sup>30</sup> One might expect that video games designed to be physically active 207 could confer health benefits, but none of the meta-analyses examining this hypothesis met 208 our thresholds for statistical credibility (see Supplementary Files 6 & 7) therefore this 209 hypothesis could not be addressed. 210

Social media was one type of exposure that showed consistent associations with poor health, with no indication of potential benefit. Social media showed strong evidence of

211

harmful associations with risk taking in general, as well as unsafe sex and substance abuse.<sup>31</sup>
These results align with meta-analytic evidence from adults indicating that social media use
is also associated with increased risk of depression.<sup>32,33</sup> Recent evidence from social media
companies themselves suggest there may also be negative effects of social media on the
mental health of young people, especially teenage girls.<sup>34</sup>

One category of exposure appeared to be consistently associated with benefits: 218 screen-based interventions designed to promote learning or health behaviours. This finding 219 indicates that interventions can be effectively delivered using electronic media platforms, but 220 does not necessarily indicate that screens are more effective than other methods (e.g., 221 face-to-face, printed material). Rather, it reinforces that the content of the screen use may 222 be the most important aspect. The way that a young person interacts with digital screens 223 may also be important. We found evidence that touch screens had strong evidence for 224 benefits on learning, <sup>26</sup> as did augmented reality. <sup>35</sup> 225

Largely owing to a small number of studies or missing individual study data, there 226 were few age-based conclusions that could be drawn from reviews which met our criteria for 227 statistical certainty. If we expand to include those reviews which did not meet this threshold, 228 there remained no clear pattern although there were some age-specific differences in 229 associations (data available in Supplementary Materials). For example, advertising of 230 unhealthy food was associated with unhealthy food choice for young children, but was not 231 statistically significant for other age groups.<sup>36</sup> Conversely, TV programs and movies were more strongly associated with lower physical activity for adolescents than for younger age groups.<sup>37</sup> Given the differences in development across childhood and adolescence and the different ways children of various ages use screens, further examination of age-based 235 differences is needed. However, in the absence of this work, our study has shown how 236 children are affected by screens in general. 237

Among studies that met our criteria for statistical certainty heterogeneity was high,

238

with almost all effects having  $I^2 > 50\%$ . Much of this heterogeneity is likely explained by differences in measures across pooled studies, or in some cases, the generic nature of some of the exposures. For example, "TV programs and movies" covers a substantial range of content, which may explain the heterogeneous association with education outcomes.

Our results have several implications for policy and practice. Broadly, our findings 243 align with the recommendations of others who suggest that current guidelines may be too 244 simplistic, mischaracterise the strength of the evidence, or do not acknowledge the important 245 nuances of the issue. 38-40 Our findings suggest that screen use is a complex issue, with 246 associations based not just on duration and device type, but also on the content and the 247 environment in which the exposure occurs. Many current guidelines simplify this complex 248 relationship as something that should be minimised. 12,13 We suggest that future guidelines 249 need to embrace the complexity of the issue, to give parents and clinicians specific 250 information to weigh the pros and cons of interactions with screens. 251

In particular, our results support the the continuing trend of guidelines moving away
from recommendations to reduce 'screen use', and instead focusing on the type of screen use.
For example, our findings suggest that guidelines should discourage high levels of social
media and internet use. Guidelines may also consider adapting recommendations that
promote the use of educational apps and video games, although these recommendations need
to be balanced against the (very small) risks to adiposity.

Our results also have implications for future research. Screen use research is extensive, varied, and rapidly growing. Reviews tended to be general (e.g., all screen use) and even when more targeted (e.g., social media) nuances related to specific content (e.g., Instagram vs Facebook) have not been meta-analysed or have not produced credible evidence. Fewer than 20% of the effects identified met our criteria for statistical credibility. Most studies which did not meet our criteria failed to provide study-level data (or did not provide sufficient data, such as including effect estimates but not sample sizes). Newer reviews were

more likely to provide this information than older reviews, but it highlights the importance
of data and code sharing as recommended in the PRISMA guidelines.<sup>41</sup> When study level
data was available, many effects were removed because the pooled sample size was small, or
because there were fewer than ten studies on which to perform an Egger's test. It seems that
much of the current screen use research is small in scale, and there is a need for larger,
high-quality studies.

Our results highlight the need for the field to more carefully consider if the term 'screen use' remains appropriate for providing advice to parents. Instead, our results suggest that more nuanced and detailed descriptions of the behaviours to be modified may be required.

Rather than suggesting parents limit 'screen use', for example, it may be better to suggest that parents promote interactive educational experiences but limit exposure to advertising.

Screen use research has a well-established measurement problem, which impacts the 276 individual studies of this umbrella review. The vast majority of screen use research relies on 277 self-reported data, which not only lacks the nuance required for understanding the effects of 278 screen use, but may also be inaccurate. In one systematic review on screen use and sleep, 66 279 of the 67 included studies used self-reported data for both the exposure and outcome variable. 280 It has been established that self-reported screen use data has questionable validity. In a 281 meta-analysis of 47 studies comparing self-reported media use with logged measures, Parry 282 et al<sup>42</sup> found that the measures were only moderately correlated (r = 0.38), with 283 self-reported problematic usage fairing worse (r = 0.25). Indeed, of 622 studies which 284 measured the screen use of 0—6 year-olds, only 69 provided any sort of psychometric properties for their measure, with only 19 studies reporting validity.<sup>43</sup> While some researchers have started using newer methods of capturing screen behaviours—such as 287 wearable cameras<sup>44</sup> or device-based loggers<sup>45</sup>—these are still not widely adopted. It may be 288 that the field of screen use research cannot be sufficiently advanced until accurate, validated, 289 and nuanced measures are more widely available and adopted. 290

There were a number of strengths and limitations to our work. Our primary goal for
this umbrella review was to provide a high-level synthesis of screen use research, by
examining a range of exposures and the associations with a broad scope of outcomes. Our
results represent the findings from 2,496 primary studies comprised of 2,026,054 participants.
To ensure findings could be compared on a common metric, we extracted and reanalysed
individual study data where possible.

Our high-level approach limits the feasibility of examining fine-grained details of the 297 individual studies. For example, we did not examine moderators beyond age, nor did we rate 298 the risk of bias for the individual studies. Thus, our assessment of evidence quality was 299 restricted to statistical credibility, rather than a more complete assessment of quality (e.g., 300 GRADE<sup>46</sup>). As such, we made decisions regarding the credibility of evidence, where others 301 may have used different thresholds or metrics. In addition, when faced with duplicate 302 outcome/exposure combinations we chose to keep the one with the largest pooled sample 303 size, assuming that this would capture the most comprehensive and most recent review. 304 Inspection of the excluded effect sizes suggests that this decision was not that impactful: our 305 results would have been almost exactly the same has we used the number of included studies 306 (k) or the most recent review by publication year. However, we provide the complete results in the supplementary material, along with the dataset for others to consider alternative 308 criteria.

Our high-level approach also means that we could not engage with the specific
mechanisms behind each association, and as such, we cannot make strong claims on the
directions of causality. These likely depend on the specific exposure and outcome. It is
tempting to draw inferences that the associations are due to screen use causing these
outcomes, but we cannot rule out reverse causality, a third variable, or some combination of
influences. Many of the individual reviews go into more detail about the strength of the
evidence for causal associations, but those judgements were difficult to synthesise across
more than 200 reviews. Readers who wish to more deeply understand one specific

relationship are directed to the cited review for that effect, where the authors could engage more deeply with the mechanisms.

We converted all effect sizes to a common metric (Pearson's r) to allow for comparisons 320 of magnitude, but acknowledge that this assumes a linear relationship between the variables. 321 Some previous research suggests that associations are typically linear. 18 However, others 322 have identified instances where non-linear relationships exist, especially for very high levels 323 of screen use. 17,47,48 Additionally, our conversion may not always adequately account for differences in study design or measures of exposures and outcomes. Care is needed, therefore, when interpreting the effect sizes. In addition, reviews provide only historical evidence which may not keep up with the changing ways children can engage with screens. While our 327 synthesis of the existing evidence provides information about how screens might have 328 influenced children in the past, it is difficult to know if these findings will translate to new 329 forms of technology in the future. 330

Screen use is a topic of significant interest, as shown by the wide variety of academic 331 domains involved, parents' concerns, and the growing pervasiveness into society. Our 332 findings showed that the influence of screen use can be both positive (e.g., educational video 333 games were associated with improved literacy) and negative (e.g., general screen use was 334 associated with poorer body composition). The interplay of these findings show that parents, 335 teachers, and other caregivers need to carefully weigh the pros and cons of each specific activity for potential harms and benefits. However, our findings also suggest that in order to aid caregivers to make this judgement, researchers need to conduct more careful and nuanced 338 measurement and analysis of screen use, with less emphasis on measures that aggregate 339 screen use and instead focus on the content, context, and environment in which the exposure 340 occurs. 341

342 Methods

We prospectively registered our methods on the International Prospective Register of
Systematic Reviews (PROSPERO; CRD42017076051) in October 2017. We followed the
Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA)
guidelines.<sup>41</sup>

Eligibility criteria. Population: To be eligible for inclusion, meta-analyses needed to include meta-analytic effect sizes for children or adolescents (age 0-18 years). We included meta-analyses containing studies that combined data from adults and youth if meta-analytic effect size estimates specific to participants aged 18 years or less could be extracted (i.e., the highest mean age for any individual study included in the meta-analysis was < 18 years). A meta-analysis was still included if the age range exceed 18 years, provided that the mean age was less than 18. We excluded meta-analyses that only contained evidence gathered from adults (age >18 years).

Exposure: We included meta-analyses examining all types of electronic screens 355 including (but not necessarily limited to) television, gaming consoles, computers, tablets, 356 and mobile phones. We also included analyses of all types of content on these devices, 357 including (but not necessarily limited to) recreational content (e.g., television programs, 358 movies, games), homework, and communication (e.g., video chat). In this review we focused 359 on electronic media exposure that would be considered typical for children and youth. That 360 is, exposure that may occur in the home setting, or during schooling. Consistent with this 361 approach, we excluded technology-based treatments for clinical conditions. However, we included studies examining the effect of screen exposure on non-clinical outcomes (e.g., learning) for children and youth with a clinical condition. For example, a meta-analysis of the effect of television watching on learning among adolescents diagnosed with depression 365 would be included. However, a meta-analysis of interventions designed to treat clinical 366 depression delivered by a mobile phone app would be excluded. Outcomes: We included all 367

reported outcomes on benefits and risks.

Publications: We included meta-analyses (or meta-regressions) of quantitative evidence. 369 To be included, meta-analyses needed to analyse data from studies identified in a systematic 370 review. For our purposes, a systematic review was one in which the authors attempted to 371 acquire all the research evidence that pertained to their research question(s). We excluded 372 meta-analyses that did not attempt to summarise all the available evidence (e.g., a 373 meta-analysis of all studies from one laboratory). We included meta-analyses regardless of 374 the study designs included in the review (e.g., laboratory-based experimental studies, randomised controlled trials, non-randomised controlled trials, longitudinal, cross-sectional, 376 case studies), as long as the studies in the review collected quantitative evidence. We excluded systematic reviews of qualitative evidence. We did not formulate inclusion/exclusion criteria related to the risk of bias of the review. We did, however, employ 379 a risk of bias tool to help interpret the results. We included full-text, peer-reviewed 380 meta-analyses published or 'in-press' in English. We excluded conference abstracts and 381 meta-analyses that were unpublished. 382

Information sources. We searched records contained in the following databases:
Pubmed, MEDLINE, CINAHL, PsycINFO, SPORTDiscus, Education Source, Embase,
Cochrane Library, Scopus, Web of Science, ProQuest Social Science Premium Collection, and
ERIC. We conducted an initial search on August 17, 2018 and refreshed the search on
September 27, 2022. We searched reference lists of included papers in order to identify
additional eligible meta-analyses. We also searched PROSPERO to identify relevant
protocols and contacted authors to determine if these reviews have been completed and
published.

Search strategy. The search strategy associated with each of the 12 databases can
be found in Supplementary File 1. We hand searched reference lists from any relevant
umbrella reviews to identify systematic meta-analyses that our search may have missed.

Selection process. Using Covidence software (Veritas Health Innovation,
Melbourne, Australia), two researchers independently screened all titles and abstracts. Two
researchers then independently reviewed full-text articles. We resolved disagreements at each
stage of the process by consensus, with a third researcher employed, when needed.

Data items. From each included meta-analysis, two researchers independently
extracted data into a custom-designed database. We extracted the following items: First
author, year of publication, study design restrictions (e.g., cross-sectional, observational,
experimental), region restrictions (e.g., specific countries), earliest and latest study
publication dates, sample age (mean), lowest and highest mean age reported, outcomes
reported, and exposures reported.

Study risk of bias assessment. For each meta-analysis, two researchers independently completed the National Health, Lung and Blood Institute's Quality
Assessment of Systematic Reviews and Meta-Analyses tool<sup>49</sup> (see Table 1). We resolved disagreements by consensus, with a third researcher employed when needed. We did not assess risk of bias in the individual studies that were included in each meta-analysis.

Effect measures. Two researchers independently extracted all quantitative
meta-analytic effect sizes, including moderation results. We excluded effect sizes which were
reported as relative risk ratios or odds ratios, as meta-analyses did not contain sufficient
information to meaningfully convert to a correlation. We also excluded effect size estimates
when the authors did not provide a sample size. Where possible, we also extracted effect
sizes from the primary studies included in each meta-analysis.

To facilitate comparisons, we converted effect sizes to Pearson's r using established formulae. Figure 1. Effect sizes on the original metric are provided in Supplementary File 2. Throughout the results section we interpret the size of the effects using Funder and Ozer's guidelines: very small (0.05 < r <= 0.1), small (0.1 < r <= 0.2), medium (0.2 < r <= 0.2), large (0.3 < r <= 0.4), and very large (r >= 0.4). These are similar to other interpretations

based on empirical data.<sup>53</sup>

445

Synthesis methods. After extracting data, we examined the combinations of
exposure and outcomes and removed any effects that appeared multiple times (i.e., in
multiple meta-analyses, or with multiple sub-groups in the same meta-analysis), keeping the
effect with the largest total sample size. In instances where effect sizes from the same
combination of exposure and outcome were drawn from different age-groups (e.g., children vs
adolescents), or were drawn using different study designs (e.g., cross-sectional vs
longitudinal) we retained both estimates in our dataset.

We descriptively present the remaining meta-analytic effect sizes. To remove the differences in approach to meta-analyses across the reviews, we reran the effect size estimate using a random effects meta-analysis via the metafor package<sup>54</sup> in R<sup>55</sup> (version 4.2.2) when 430 the meta-analysis's authors provided primary study data associated with these effects. When 431 required, we imputed missing sample sizes using mean imputation from the other studies 432 within that review. From our reanalysis we also extracted  $I^2$  values. To test for publication 433 bias, we conducted Egger's test<sup>56</sup> when the number of studies within the review was ten or 434 more,<sup>57</sup> and conducted a test of excess significance.<sup>58</sup> We contacted authors who did not 435 provide primary study data in their published article. Where authors did not provide data in 436 a format that could be re-analysed, we used the published results of their original 437 meta-analysis. 438

Evidence assessment criteria. Statistical Credibility: We employed a statistical classification approach to grade the credibility of the effect sizes in the literature. To be considered 'credible' an effect needed to be derived from a combined sample of >1,000 participants<sup>59</sup> and have non-significant tests of publication bias (i.e., Egger's test and excess significance test). We performed these analyses, and therefore the review needed to provide usable study-level data in order to be included.

Consistency of Effect within the Population: We also examined the consistency of the

effect size using the  $I^2$  measure. We considered  $I^2 < 50\%$  to indicate effects that were relatively consistent across the population of interest.  $I^2$  values of > 50% were taken to indicate an effect was potentially heterogeneous within the population.

Direction of Effect: Finally, we examined the extent to which significance testing suggested screen exposure was associated with benefit, harm, or no effect on outcomes. We used thresholds of P < .05 for weak evidence and  $P < 10^{-3}$  for strong evidence. An effect with statistical credibility but with P > .05 was taken to indicate no association of interest.

Deviations from protocol. As described above, we have summarised the
meta-analytic findings from all included systematic reviews. In our protocol, we originally
planned to also conduct a narrative synthesis of all systematic reviews, even those without
meta-analyses. However, we determined that combining results from the meta-analyses alone
allow readers to compare relative strength of associations more easily. Readers interested in
the relevant systematic reviews (i.e., without meta-analysis) can consult the list of references
in Supplementary File 4.

We altered our evidence assessment plan when we identified that, as written, it could not classify precise evidence of null effects (i.e., from large reviews with low heterogeneity and low risk of publication bias) as 'credible' because a highly-significant *P*-value was a criteria. This would have significantly harmed knowledge gained from our review as it would have restricted our ability to show where the empirical evidence strongly indicated that there was no association between screen use and a given outcome.

#### 66 Data availability statement

All data for this review are available from the authors' GitHub repository

(https://github.com/motivation-and-Behaviour/screen\_umbrella) or from the Open Science

Foundation (https://osf.io/3ubqp/).

# 470 Code availability statement

All code used in these analyses are available on the authors' GitHub repository (https://github.com/motivation-and-Behaviour/screen\_umbrella).
